Supporting Information

ABSTRACT: *Crocodylus niloticus* is found in 26 African countries including Ethiopia, the largest recorded specimen measuring 17.0 feet Nile crocodile from the Gambela Upeno River in 1969. Its presence and absence also depend on the climatic conditions and the environment (i.e. the landscape for basking and feeding). In Ethiopia, Nile crocodiles have a mating period during September to October, Nesting occurs in the dry season (i.e. March/April months). Over the period of 2007-2016 an average of 201,000 Crocodylus niloticus skins were exported globally per year, with an increasing trend over the period 2007-2016. Besides the management problems, at Arba Minch Crocodile Ranch, Nile crocodiles are suffering from nutritional abnormalities and health problems. The diseases of the Nile crocodile are classified as infectious (transmissible) and non-infectious (non-transmissible). A transmissible crocodile disease includes bacterial, viral, fungal, protozoan, and parasitic diseases; non-transmissible crocodile diseases are nutritional, toxic poisonings and metabolic disorders; other diseases like nutritional bone diseases and skin lesions are the major health problems at Arba Minch Crocodile Ranch. The main aim of this review is to highlight the major diseases and management status of *Crocodylus niloticus* in Arba Minch ranches, Ethiopia. In conclusion, the Arba Minch Crocodile Ranch (AMCR) should exercise care and caution when introducing hatchlings from the wild into the Ranch and enhance its husbandry methods to reduce the occurrence of infection and disease. It must also work with professionals and research groups.

Keywords: Arba-Minch, *Crocodylus niloticus*, Diseases, Nile crocodile.

INTRODUCTION

Reptiles are considered ectothermic (Seebacher, 1999, Modesto and Anderson, 2004) and due to their environmental thermal limit, most reptile species distribution tends to be near the tropics (Summers, 2015). Crocodiles are classified as the largest reptiles grouped under family Crocodylidae (Huchzermeyer, 2003). They belong to the great group called archosaurs (ruling reptiles), which also included extinct thecodonts. Crocodilians of today are the most social reptiles (Shine, 1998) all belong to the clade Eusuchia (Summers 2015); For the last few decades, and until quite recently, 23 species of modern crocodilians in eight genera were recognized currently there are 27 species in nine genera (Grigg, 2015). Which comprises of 27 species and sub-species, all belonging to a single-family called the Crocodylidae (Summers 2015). When the taxonomy is resolved, there are likely to be ~30 species recognized (Grigg, 2015).

Crocodiles are widespread throughout sub-Saharan Africa (Leslie and Spotila, 2001). There are five species of crocodiles in Africa, the African dwarf crocodile (*Osteolaemus tetraspis*), the Central African slender-snouted crocodile (*Mecistops leptorhynchus*), the West African slender-snouted crocodile (*Mecistops cataphractus*), the West African crocodile (*Crocodylus suchus*) and the Nile crocodile (*Crocodylus niloticus*) (Shirley et al., 2018). The Nile crocodile is amongst the largest and best known biologically of all the crocodilians. Nile crocodiles are widely distributed throughout sub-Saharan Africa, and historical records indicate its range formerly extended into southern Israel and Jordan. The species was also established on the Comoros Islands and still exists in Madagascar (Ross, 1998).

The Nile crocodile was once abundant in Ethiopia’s rivers and lakes. By 1971, the head of the Wildlife Conservation Department had already considered the Nile crocodile to be seriously depleted but they were protected only in reserves like Omo Game (Nechsar National) Park. Subsequently, in 1972 commercial hunting of crocodiles was prohibited in Ethiopia and the Nile crocodile was listed as a game animal that could be hunted under permit only. Ethiopia ratified the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), in 1989. The Nile crocodile was transferred from Appendix I, the highest order of protection, under the convention, to Appendix II to allow an export quota.
for ranched skins (referring to crocodiles raised from wild-collected eggs and/or hatchlings). The initial export quotas approved by CITES were 9370 for 1990 and 8870 for 1991-92 (Whitaker, 2007), but this has reduced to 3000 for ranched skins for 2018 as well as a quota of 5 trophy hunting (Isberg et al., 2019).

A ranching program for Crocodylus niloticus was implemented in Ethiopia in 1985 when the government created Arba Minch Crocodile Ranch (AMCR) (Shirley et al., 2014). The mortality rate of Crocodylus niloticus at AMCR of hatchlings collected from wild have a very high mortality rate up to 67.9% basically from hatchlings, 1-year-old, and juveniles (Whitaker, 2007; Shirley et al., 2014). Main factors affecting the production management of Crocodylus niloticus and health-related problems that decrease the number (number of mature individuals are 50,000-70,000). Some of the lives threatening factors of Nile crocodiles are urban sprawl, environmental pollution, and habitat destruction, subsistence agriculture and deforestation, and diseases (Isberg et al., 2019).

The Crocodiles in AMCR were provided mainly with feed items like fish and meat. The pathological finding was most frequently arise from nutritional deficiency as a result of crocodiles being fed meat meal, such as frozen fish and frozen meat without a bone meal. There is known to be deficient in important minerals and vitamins (Gilber, 2000). Skin lesions were the second most common problems observed at AMCR after paralysis of hind legs (Shirley et al., 2014). Therefore, this was prepared to review the major diseases and management status of Crocodylus niloticus in Arba Minch ranches, Ethiopia.

**Husbandry and breeding of Nile crocodile**

Understanding the habitat requirements and habitat use of a specific Nile crocodile population requires a combination of understanding the specific landscape mosaic dynamics that the population is found in and the resource requirements of the selected Nile crocodile (Champion and Downs, 2015). Its presence and absence also depend on the climatic conditions and the environment i.e. the landscape to basking and feed (Botha et al., 2011). In farm situations, the basic requirements for the well-being of farm crocodiles include ensuring that: 1. appropriate and sufficient food and water are provided to sustain health and vitality; 2. sufficient area is provided to maintain well-being and to allow crocodiles to exhibit normal behavior; 3. they are protected from predation; 4. they are protected from disease, including disease that can be exacerbated by management practices; 5. they are protected from extremes of climate, particularly during certain phases of their lives; and 6. pain, distress, suffering, and injury are minimized or avoided (Anon, 1992; Tosun, 2013). The mean body temperature of a crocodile is 25.6°C and a range of 6 degrees, with fluctuations from the mean of -2.6 to +4°C. Under optimum raising conditions, with adequate temperatures, hatchlings have high metabolic rates, high food requirements, and they grow rapidly; in countries with "cold" winters (e.g. USA), crocodile hatchlings are grown very successfully in heated sheds, but not all species appear to require or can tolerate high and constant temperatures. Some require a mosaic of temperatures, where they can spend part of their life, rather than the whole day with body temperatures in the 30-33°C range (Manolis and Webb, 2016).

**Ranching Nile crocodiles**

Ranching is a commercially viable strategy for crocodile farming which is widely used and demonstrates accepted conservation advantages. Ranching entails harvesting crocodile eggs from wild and incubating them to produce hatchlings (Khosa et al., 2012) it can also include the harvesting of hatchlings immediately post-hatching. The collections of eggs, hatchlings, and juveniles from the wild give natural populations a conspicuous economic value (Luxmoore, 1992; Thorbjarnarson et al., 1992; Whitaker, 2007). In Ethiopia, there are two Crocodile ranches, the State-owned Arba Minich Crocodile Ranch (AMCR) and the privately owned, Blen Development PLC, AMCR was created at the mid of 1984 and Blen was created in the mid of 2006 (Whitaker, 2007; Mahammed, 2008).

**Food and feeding behavior of Nile crocodile**

Crocodylus niloticus has a similar ontogenetic shift in diet to that of other crocodilians (Wallace and Leslie, 2008). The powerful enzymatic digestive juices of crocodiles completely digest bones, hooves, and feathers but being poikilothermic animals, digestion is promoted by higher temperatures. Juveniles feed on insects, spiders, snails, gastropods, and mussels in the shallows and onshore. Young crocodiles feed mostly on toads, frogs, and small fish such as Clarias, Labeo, and Tilapia species (Whitaker, 2007; Furstenburg, 2008). With age the diet changes to catfish (barbel) and larger mammals up to the size of young giraffe, buffalo, and elephant. On average catfish comprises 70% of the diet of adult Nile crocodile. During summer a 4 m adult will consume a large meal once in 2-3 weeks. Sub-adults of 1.5m eat once a week while juveniles feed daily. Carrion is taken only when fresh food is not available. It is estimated that up to 60% of the food intake is converted to fat for storage in the tail and trunk (Bolton, 1997; Johan and Frits, 2000; Davis, 2001; Furstenburg, 2008).

**Reproduction In Nile crocodiles**

Copulation takes place in water and all species lay eggs (Bolton, 1997). Reproductive females had a plasma testosterone surge corresponding to the time of courtship and mating. Both reproductive and non-reproductive females showed increased plasma progesterone at several times of the year (Kofron, 1990). Courtship and mating occurred in water during the day, usually directly in front of the shared basking ground (Kofron, 1991). Gender assessment in crocodilians is typically achieved by digital examination of the cranio-ventral cloaca; males have a penis while females have a clitoris. The penis may be exteriorized for visual examination if there is doubt on palpation. Adult male crocodilians typically grow to a larger size than females (Pooley, 1982; Kofron, 1991; Timothy, 2018). In Ethiopia the mating period for...
Nile crocodiles is September/October, nesting occurs in the dry season of December/January, and hatchling occurs at the onset of the rainy season of March/April months. Range and average clutch size are 25-70 eggs; average: with an average size of 45 for Lake Chamo, in the south of Ethiopia. Clutch size increases and is directly proportional to female size and age, with average fertility rates for first nesters 20 to 50%, increasing to 80 to 90% for older and mature females (Whitaker, 2007).

**Normal health conditions of Nile crocodiles**

Husbandry techniques are continually evolving to ensure animals are maintained in good health. There are major approaches to assessing the normal health status of crocodiles in ranches; anatomical and physiological assumptions, health correlations such as body condition, growth rates, and size, survival rates (Isberg et al., 2009), Frequency of injuries, disease incidence, parasite incidence, reproductive performance; biochemical indicators (such as comparative corticosterone levels, which are an indicator of stress) (Elsey et al., 1990a,b; Turton et al., 1997; Franklin et al., 2003; Isberg et al., 2009, 2013; Finger et al., 2015); behavioral observation and stimulus-response. Over and above genuine concerns about animal welfare, the media is often used to promote information that is deliberate manipulation of factual evidence (Manolis and Webb, 2016). Husbandry strategies for different ages and sizes of crocodilians have evolved separately in different farms and for different species; however, some fundamental principles can be applied to most, if not all, species. General considerations like suitable incubation and hatchling characterize, initiation of hatchling feeding, treatment of hatchlings, nutritional deficiencies and imbalances, metabolic rate and temperature, water quality, effects of hatchling size on growth, effects of sex on growth, density and social behavior (Huchzermeyer, 2003).

**Economic importance of rearing Crocodylus niloticus**

Over the past five decades, the captive rearing and managed harvests of crocodilians have been held up as a success story in the search for balanced, sustainable use of wildlife and the generation of wildlife products for international trade (Thorbjarnarson, 1999). Wild animals and their derivatives are traded worldwide to meet demands for food, clothing, decorative items, traditional medicines, and pets (Challander et al., 2015). The overall volume of world trade in classic crocodilian and caiman skins has been variable over the 10 years 2007 to 2016, with an average of 1.44 million skins exported annually. Over the period 2007-2016, an average of 201,000 Crocodylus niloticus skins were exported globally per year, with an increasing trend over the period 2009-2016 (Caldwell, 2018). In 2016, Zambia was the leading (112,434 Crocodile skins) exporter of Nile crocodile skins to the global market. Data provided by Ethiopian Wildlife Conservation Authority (EWCA), show that Ethiopia, exported 594, 492, 77, and 400 Crocodile skins in 2007, 2008, 2011, and 2012, respectively. The country’s crocodile skin export capacity is declined due to international market in the years 2010, 2015, and 2016 to 4, 6 and 7 skins, respectively and as the report shows there was Zero export of skin in the years 2009, 2013 and 2014 (Caldwell, 2018). In 2017, Crocodile hatchlings can be sold at USD 2 each to foreign investors, 15 birrs (USD 0.75) to Ethiopian investors, and 5 birrs (USD 0.25) to farmers for quantities over 100. Crocodile eggs are sold at half those prices. The Nile crocodile is also hunted by foreign tourist hunters for a USD 2000 trophy fee (Whitaker, 2007; Shirley et al., 2014; Nisagurwe, 2017). Crocodiles are not only involved in the skin trade but also traded as live animals as crocodile meat and for their teeth (Caldwell, 2018).

**Constraints to Nile crocodile management**

Crocodile ranch management in Ethiopia requires a formal management plan in terms of national legislation. The species is currently subject to both consumptive (e.g., ranching and trophy hunting) and non-consumptive (e.g., tourism) uses, as well as implicated in human-wildlife conflict. Crocodiles are theoretically managed by federal, state, zonal, and woreda (district) administrations under national laws for biodiversity protection and utilization, ranching, and trophy hunting. A formal management plan should also provide a framework for overcoming some current management deficiencies but this is not yet the case, in Ethiopia (Whitaker, 2007; Shirley et al., 2014). Local threats for crocodile conservation management includes; (a) lack of regulation enforcement, (b) illegal fishing gear and unsustainable growth of the fishing industry, which has resulted in overfishing, a decline in a population of the main target species to almost non-viable levels and the apparent extinction of one of them; (c) increase in cattle grazing such that many areas previously used by crocodiles for basking and nesting have been destroyed. (d) Cultivation up to the lakeshore which is impacting negatively on crocodile behavior, recruitment, and survival. Droughts due to climate change and other effects will likely increase this threat (Whitaker, 2007). In addition to management problems in the wild, Nile crocodiles are suffering from nutritional abnormalities and health problems at AMCR. The main health problems are a combination of mal-nutritional diseases and skin diseases. The mortality rate of almost 70% of hatchlings and juveniles has been ascribed to nutritional bone diseases caused by continuous feeding of meat and fresh frozen fish meat. AMCR harvested more than 8890 crocodile skins from 1982-1998 E.C, they would earn more than USD 3,744,000.00 if they harvest first-grade skin, but the reality is 769,000 ETB (USD 1 was 8 ETB when the author reports the data) (Shirley et al., 2014).

**Common diseases of Nile crocodiles**

According to Radostits et al. (2006) definition of animal diseases, crocodile diseases are 'inability to perform physiological functions at normal levels even though nutrition and other environmental requirements are provided at adequate levels'. The diseases of Nile crocodiles are classified as infectious (transmissible) and non-infectious (non-
transmissible). A transmissible crocodile disease includes bacterial, viral, fungal, protozoan, and parasitic diseases; the rest are nutritional, toxic poisonings and metabolic disorders are non-transmissible crocodile diseases (Huchzermeyer, 2003).

**Infectious diseases of Nile crocodile**

Ippen and Zwart (1996) postulated as the most reptiles in captivity were taken from the wild. Their infectious and parasitic diseases will have been imported with them, and that husbandry practices would have an influence on disease outbreaks there are several crocodile-specific viral and bacterial infections, some of which may even be species or genus specific. However, their present distribution may also be due purely to geographical limits. The specificity of parasites also varies. Besides, there are many non-specific infections, particularly bacterial and fungal (Huchzermeyer, 2003).

**Bacterial infections**

Only a few bacteria cause specific diseases in crocodiles, and even fewer of these are crocodile-specific. However, many different species of bacteria can cause nonspecific septicaemias. These bacteria are recruited either from the aquatic environment, the intestinal flora or from food contaminants, particularly where raw meat is used as feed. All septicaemias, specific and non-specific, are triggered, if not caused, by stress. Bacteria are allowed to escape under severe stress from the intestine into the blood circulation, and if the stress continues, the resultant immune suppression prevents the crocodile from overcoming the initial escape and allows the bacteria to gain a foothold (Huchzermeyer and Cooper, 2000). Some bacterial genera that cause infection in Crocodiles are included in this review.

**Mycoplasmosis**

Mycoplasmas were isolated from lungs and synovial fluid of the Nile crocodiles and the isolates were identified as Mycoplasma crocodyli (Kirchhoff et al., 1997). The joints of infected crocodiles were had swollen joints and filled with excessive quantities of turbid fluid, in chronic cases with dry fibrinous exudeate, and some of the animals were found to have lesions of pneumonia. As *M. crocodyli* is a relatively recently described (in Zimbabwe in 1995) pathogen, aspects of other Mycoplasma spp. (Mohan et al., 1995). *M. crocodyli*, as with other Mycoplasmas, lacks true cell walls and has a typical fried-egg appearance on solid medium, but grows relatively well in an artificial medium. Glucose and mannose are both fermented, and cholesterol or serum is required for growth. It is one of the few Mycoplasma spp. that fulfills Koch’s postulates for disease causation (Kirchhoff et al., 1997). Serological assays are often used to test animals for exposure to infectious agents and include many of the common laboratory procedures such as the ELISA, agglutination, precipitation, neutralization, etc. Indirect ELISA (iELISA) for the detection of antibodies (Ab) to *M. crocodyli* infection in crocodile sera was developed using Ag and anti-crocodile conjugate (Dawo and Mohan, 2007). An immune-blotting protocol for the detection of antibodies to *Mycoplasma crocodyli* was developed using the sonicated antigen of the reference strain 266/93. Immunoblotting detected nine reacting antigens, of which the 33 and 40 kDa antigens were immune-dominant (Dawo and Mohan, 2008). The complete genome sequence of *M. crocodyli* has recently been reported but, although at least five potential virulence factors have been identified, their role and significance are still unclear (Brown et al., 2011), polyarthritis is the best described clinical and pathological sign including progressive weakness, ranging from stiffness to complete immobility. Different stages of exudative polyarthritis are encountered at necropsy, ranging from turbid mucous containing *Mycoplasma* spp. in acute and sub-acute cases, to yellow, inspissated exudates in chronic cases. Histopathological changes include inflammatory edema of the surrounding tissue, necrosis of the superficial layers of the synovial membrane, and fibrin deposition, lymphocytic infiltration, and fibrosis of the joint capsule. Apart from polyarthritis, the organism also triggers pneumonia, histo-pathologically characterized by consolidation and edema of affected areas, with a white blood cell (particularly poly-morpho-nuclear cells and mononuclear cells) and erythrocyte infiltration (Mohan et al., 1995; Kirchhoff et al., 1997; Huchzermeyer and Cooper, 2000; Huchzermeyer, 2003).

In general, mycoplasmosis control can be divided into three important sectors, namely vaccination, medication, and keeping disease-free animals (Desrosiers, 2001; Ley, 2006; Caswell and Archambault, 2008; Kleven, 2008). These are generally not mutually exclusive and are used in combination as required. Medication, including parenteral treatment of diseased crocodiles and/or in-feed treatment, have been performed during crocodile mycoplasmosis outbreaks, but treatment failures (Mohan et al., 2002), reports on antimicrobial resistance (Aylng et al., 2000, Reinhardt et al., 2002, Rosenbusch et al., 2005, Antunes et al., 2007) and high costs eliminates this as a long term control strategy (Grobler, 2013). Vaccination against mycoplasmosis is widely used in commercial pig, poultry, and cattle production systems, particularly in multi-age set-ups because it often is the only viable long-term option. Both inactivated and live-attenuated vaccines have been tested and are currently in use (Grobler, 2013).

**Chlamydiosis**

Chlamydiosis is a disease in farmed Nile crocodiles caused by chlamydiae closely related to *Chlamydia psittaci*, but probably a different species. There are two forms: acute hepatitis and chronic conjunctivitis (Huchzermeyer et al., 1994). On post-mortem examination, the liver is found to be pale, mottled, and enlarged and the spleen slightly enlarged. There are mild ascites and a severe hydro-pericardium: the most severe histopathological changes are found in the liver: a severe portal to diffuse lymphoplasmacytic hepatitis with congestion, mild bile duct proliferation, vascular degeneration of the hepatocytes and multifocal to coalescing necrosis. Numerous colonies of intra-cytoplasmic organisms are present in the hepatocytes (Huchzermeyer, 2003). The mode of transmission is not identified, yet. But the contamination of surface water by wild carrier crocodiles is suspected. The diagnosis is based on the demonstration of the agents either microscopically or by culture (Huchzermeyer, 2002). An investigation into the cause of acute mortality in the farmed
hatching, *Crocodylus niloticus* led to the isolation of chlamydia from the livers of affected animals (Huchzermeyer et al., 1994). Both forms of chlamydiosis respond to tetracycline (Huchzermeyer, 2002); Terramycin soluble powder (10g/kg of feed), or pure oxytetracycline (1g/kg of feed) (Huchzermeyer, 2003). The prevention of chlamydiosis must be based on stress prevention as well as on strict hygienic measures, such as the use of borehole or well water in the rearing section, as well as the disinfection of footwear when moving from section to section (Huchzermeyer, 2002; 2003).

**Salmonellosis**

Salmonellosis is caused by bacteria of the genus *Salmonella* and manifests itself either as enteritis, particularly in hatchlings (Huchzermeyer, 2003). Reptiles may be considered a natural reservoir for *Salmonella* bacteria, but except for pet turtles, the role of poikilothermic vertebrates in the transmission of *Salmonella* to other animals and men is common (Madsen, 1996). From 1985-1994 scientists, Huchzermeyer and Agnagna were isolated Salmonella from 148 out of 173 from farmed Nile crocodiles (Huchzermeyer, and Agnagna, 1994; Walt et al., 1997). A study from Zimbabwe published that the prevalence of Salmonella was 30% in fresh and 20% in the frozen meat samples (Madsen, 1996), but the prevalence of the bacteria has not been adequately studied. Bacterial septicemia is often precipitated by severe stress with frequent change in temperature, the ongoing infection may cause depression and anorexia, the enteritic form of the disease may either cause fibrinous exudation and occlusion of the intestine, or diarrhea, hemorrhagic enteritis due to *S. choleraesuis* (Ocholi and Enurah, 1989; Huchzermeyer, 2003). Diagnostic procedures are performed by bacterial culture of blood, feces, or synovial aspirate. The treatment of clinical cases comprises oral or parenteral administration of an antibiotic selected by an antibiogram and the elimination of the precipitating stressor(s). The prevention methods require strict sanitary feed, hygiene, washing with a detergent to remove protective layers of fat, and vaccinating via a calf paratyphoid vaccine (Huchzermeyer, 2003).

**Non-specific septicaemias**

The non-specific septicaemias of crocodiles are caused by a large variety of bacteria of enteric or environmental origin, many of which are opportunistic rather than obligatory pathogens, mostly part of the normal intestinal flora, although the intestinal flora of farmed crocodiles may be modified by antibacterial treatments and the introduction of potential pathogens when feeding meat, particularly from farm mortalities (Huchzermeyer, 2003). Septic wounds rarely lead to septicaemias and this adds support to the hypothesis of the enteric origin of septicemia in crocodiles (Huchzermeyer and Cooper, 2000). Some of the isolated cases of septicaemias in Nile crocodiles (Table 1). The course of the disease depends on the environmental temperature (the course is fast in hatchlings kept at 32–34°C, but slows in juveniles at low temperatures, while it can take several months in adults) and the size of the affected crocodiles. In some chronic cases, the affected crocodiles develop white patches around the nostrils and eyes, as well as on the dorsal surface of the body and limbs. In advanced cases, the likelihood of a treatment being successful is minimal. For the prevention of septicaemias, it is necessary to maintain optimal temperature (Huchzermeyer, 2003).

**Viral Diseases of Nile crocodiles**

The etiology of reptilian viral diseases can be attributed to a wide range of viruses occurring across different genera and families. Forty to fifty years ago, studies of viruses in reptiles focused mainly on the zoonotic potential of arboviruses in reptiles and much effort went into surveys and challenge trials of a range of reptiles (Ariel, 2011). The diagnosis of viral infections should be based on the presence of serological tests and the isolation and characterization of the virus. Regarding the crocodile viruses, there is a serious problem. None of them can be isolated in embryonated chicken eggs, nor can they be grown in any of the cell culture lines presently in use. Nobody has yet isolated or established crocodile embryonic cell lines that could be used for this work (Huchzermeyer, 2003).

**Adenoviral Infection**

These viral infections most commonly affect the liver of hatchlings under 5 months, less often the intestines and pancreas, and sometimes the lungs as well, but rarely all at the same animal (Jacobson et al., 1984; Foggin, 1987; 1992). Diagnosis of adenovirus is now largely done by molecular tools such as PCR directly on swabs or organs followed by...
Crocodylus niloticus

3). There is no specific treatment against crocodile pox infection. However, a crude autogenous vaccine prepared from scabs from affected animals reduced the recovery.

Wellehan Huchzermeyer et al.

produced into the rearing environment (Riley 1994; R Pandey et al.). Lesions on the eyelids may cause blindness, and lesions on the head may cause a shrinking of the skin, leading to deformities (Foggin, 1987; Horner, 1988). The skin lesions appeared as dark brown, crusty pox-like lesions up to 3mm in diameter, with a sharply outlined central depression. The lesions are situated between the scales and can occur over the entire body. They intended to be concentrated mainly on the ventral and lateral surfaces of the body and tail, the upper and lower surfaces of the limbs, and around the jaws and eyes (Huchzermeyer et al., 1991). It is presumed that the virus can be carried and shed by clinically healthy carriers. Adult breeding stock on the farm also is a possible source of the virus. While the virus could possibly be transmitted by mosquito bite, it is much more likely to be transmitted by contaminated water, or the acquisition of hatchlings from a farm where the disease had occurred (Horner, 1988; Huchzermeyer et al., 1991; Huchzermeyer, 2003). There is no specific treatment against crocodile pox infection (Huchzermeyer, 2003). A crude autogenous vaccine prepared from scabs from affected animals reduced the recovery time (Horner, 1988), but there is the danger of causing generalized infection amongst unvaccinated individuals, when the live vaccine virus is introduced into the rearing environment (Foggin, 1992). The prevention of crocodile pox infection is based on avoiding the use of potentially contaminated water and the avoidance of stress, particularly heat stress (Huchzermeyer, 2003)

Other viral infections

Other viruses found in Crocodylus niloticus, with less economic importance, include Coronavirus-like particles (found by transmission electron microscopy in negatively stained feces of four 2-3-year-old crocodiles at a farm with severe mortality in that age group; Filamentous forms of influenza C virus (found by transmission electron microscopy in negatively stained feces of eight Nile crocodiles (length 31-81cm) from one farm associated with high mortality over 1 month (Huchzermeyer et al., 1994); Newcastle disease virus, although it does not cause clinical disease in crocodiles. But, when Nile crocodiles are fed fowl that had died from Newcastle disease, they seroconvert; Paramyxovirus was found in the feces of a single crocodile from a farm where no poultry had been fed (Thomson, 1972; Huchzermeyer et al., 1994; Pfitzer et al., 2000).

Parasitic diseases of Nile crocodile

Nile crocodiles are infected by many ecto and endo-parasites, with trypanosome being the most common. The trypanosomes of crocodiles are harmless flagellate blood parasites transmitted by biting flies and possibly also mosquitoes (Hoare, 1928; 1929; 1931). Other blood parasites that have been isolated from Nile crocodiles are Hepatozoon species such as Hepatozoon petite and Hepatozoon sheppardi (Travassos Santos Dias, 1952). Coccidiosis in Nile crocodiles is caused by a complicated parasitic protozoan and several coccidian parasites of crocodiles have been described from fecal suspensions according to their oocyst morphology such as Eimeria spp. (Hoare, 1932; Huchzermeyer, 2003), Goussia spp. (Gardiner et al., 1986) and Cryptosporidia (Siam et al., 1994; Lane and Mader, 1996) (Table 2). The pentastomid parasites of chelonians and crocodilians are currently divided into the family Sebekidae and Subtriquetridae (Riley et al., 1990; Riley 1994; Riley and Huchzermeyer 1996; Riley et al., 1997; Junker and Bookmker, 2006; Junker et al., 2016). Pentastome assemblages comprised seven species in three Sebekid genera, Alofia Leiperia, and Sebekia, for example, Alofia niloticici (Riley and Huchzermeyer, 1995), A. simpsonii (Riley, 1994), Leiperia cincinnalis (Sambon, 1922), Sebekia cesarisi (Giglioli, 1922), S. minor (Junker et al., 1998; 2016) and S. okavangoensis (Riley and Huchzermeyer, 1995), Subtriquetra rileyi (Junker et al., 1998).

In the lungs, the parasites suck blood and thereby can cause infection and inflammation. In cases of stress septicemia, the bacteria present in the blood can invade the lung tissue in the lesions caused by the pentastomes, and thus create the abscesses found associated with pentastome infestations. In severe infestations, pentastome eggs may be found in the host’s feces. On post-mortem examination, the parasites are found in the larger air passages of the lungs. The treatment requires antiparasitic Dermotax® (Doramectin 1%) dose of 1 ml per 50 kg of body mass, while Ivermectin at effective doses is toxic. For prevention, it is vital to control the fresh fish food as a fish are intermediate hosts, and distress prevents Nile crocodiles from forming lung abscess (Huchzermeyer, 2003).

**Fungal Infections in Nile crocodiles**

Crocodiles are farmed mainly for their skin, and most fungal infections are affecting the skin of Nile crocodiles (in both farms and wild). Many of the fungi involved in these infections are part of the normal intestinal flora and are excreted daily with the feces into the water (Huchzermeyer, 2003). Normally, the fungi are inhibited in the intestine by the bacterial flora. If the latter is suppressed by prolonged antibacterial treatment, the fungi can multiply more freely. Reported cases of most fungal diseases were diagnosed by histopathological examinations of the host tissue (Gilber, 2000). The tissue reaction to fungal infections is granulomatous and not exudative as it is in most localized bacterial infections. The granulomata are characterized by the presence of multinucleated giant cells (Huchzermeyer, 2003). Beauveria bassiana (Keymer, 1974) has been isolated from the lungs of captive Nile crocodiles and Trichosporon species has been isolated from the tongue and gingivae of a captive Nile crocodile (Kuttin et al., 1978). Systemic and respiratory infections are often diagnosed too late for treatment to be considered, Oral mycosis and gastro-intestinal mycosis are treated with antifungal injections, whilst skin dermatophytes are treated by injections and topical routine of administration. Avoiding excessive fungal build up prevents the diseases and an aggressive antibiotic also delays the development of fungus (Huchzermeyer, 2003).

**Non-infectious diseases of Nile crocodiles**

Captive crocodiles frequently are given a monotonous diet, which may be deficient in one or more essential constituents. This may lead to deficiencies of certain minerals and vitamins that used for fast growth rate, and this can further accentuate potential imbalances in their artificial nutrition. These also enhance some conditions like osteomalacia, rickets, secondary hyperparathyroidism, metabolic bone disease, fibrous osteodystrophy and osteoporosis, diaphanous teeth, Vitamins deficiencies (Vitamins A, B1, C, D, E, and K), mineral deficiencies (Ca++, K+, P and Zn), and hypoproteinemia. Poisoning occurs not only through the deliberate or accidental ingestion of substances but also human activities such as organophosphates poisoning from pesticides, algicides, algal toxicity, rodenticides, radionucleoids, and fire ants delays the production of Nile crocodiles (Huchzermeyer, 2003).
CROCODILE DISEASES AT ARBA MINCH CROCODILES RANCH, ETHIOPIA.

Arba Minch Crocodile Ranch (AMCR) is found in Arba Minch, where it is located 500 km south of Addis Ababa with an altitude range from 1100-2800 m above sea level. Arba Minch district covers 173,108 hectares and has three climatic zones; lowland (37.5%), midland (40.5%) and highland (22%) areas with an average mean temperature range of 15°- 31° C. The area has grasses, bushlands and deciduous forests with sandy and clay soil type (Kebede, 2006). In order to conserve and optimally utilize the Nile crocodile ranch was established in 1984 (Yeshdenber, 1994; Graham and Gebre, 1997; Kebede, 2006; Whitaker, 2007; Shirley et al., 2014).

Although crocodile ranching practiced in Ethiopia, for almost 35 years, it is difficult to find any work on health problems of crocodiles and management activities. The government of Ethiopia collaborated with CSG to study the crocodile ranching in the country and highlighted the documents housed at EWCA that focused mainly on surveys and conservation issues. Mahammed (2008) researched crocodile health at AMCR but his report remains unavailable. In his cross-sectional study, no parasites or their ova were found (n= 80; 60 Juvenile and 20 Adults). Clinical investigation of the same animals showed 20/80 abnormalities, predominantly hind legs, and skin lesions.

The clinical assessment of the previous study 25% (20 out of 80) had clinical abnormalities; 5 of the crocodiles were unable to move on dry land during basking, showing paralysis of two hind legs and slight swelling of the tail muscle, and yet were able to swim ‘normally’. A further 5 animals showed multiple skin lesions, 5 showed circling movement while swimming in the water, and the remaining animals were dead before the examination. During post mortem examination, there was excessive yellow and hard fatty accumulation was identified in tail muscles. 6.25% (5 out of 80) had multiple skin lesions which were multiple and dominated by small erosions, on the ventral aspect of the abdomen and One crocodile showed ulcerative types of skin lesion over its head, neck, back, and tails. The sick crocodiles were found dead after 2-4 weeks. And showed accumulation of fluid in the pericardial sac slightly enlarged pale heart and liver. Most of these problems were observed on juveniles (young) and yearlings and occurred after they were provided with frozen fish meat (Mahammed, 2008).
Nutritional Diseases of Nile crocodiles In AMCR

Nutritional bone disease is an umbrella term that covers a range of related conditions and names, such as osteomalacia, rickets, metabolic bone disease, fibrous osteodystrophy, and osteoporosis. Metabolic bone disease shifts the emphasis on calcium (Ca) and phosphorus (P) metabolism. Osteo-malacia and fibrous osteodystrophy are the terms for the condition in young hatchlings where their bones fail to harden due to the lack of calcium. Rickets applies to malformations of the growing bone when due to the lack of vitamin D3, the bones also fail to harden and become bent. Osteoporosis occurs in older juveniles and adults, where the already hardened bone structure becomes weakened by the withdrawal of calcium for metabolic needs (Huchzermeyer, 2003). The Crocodiles in AMCR were provided mainly with feed items like fish and meat. The meat that was used as a feed for crocodiles includes meat from dead old horses, donkeys, dogs, cattle, sheep, goats, and crocodiles themselves. The crocodiles are fed three times per week or once every two days while they were young. The pathological finding was most frequently arising from nutritional deficiency as a result of crocodiles being fed meat meals, such as frozen fish and frozen meat without a bone meal (Mahammed, 2008). There is known to be deficient in important minerals and vitamins (Gilber, 2000).

Feeding frozen fish has two limitations; the first is that fresh and frozen fish often contain large amounts of the enzymes thiaminas. Freezing appears to increase the concentration of the thiaminas in the tissue of fish, which destroys the vitamin B1 (thiamine); the second problem is an accumulation of fats in the subcutaneous and intramuscular tissue leading to paralysis of the legs, which is caused by particularly oily fish meals (Huchzermeyer, 2002; Huchzermeyer, 2003). For the treatment of nutritional bone disease, it is necessary to rectify the diagnosed deficiency, usually that of calcium. If the affected hatchlings are too weak to feed by themselves, they can initially be dosed or injected intraperitoneal (IP) with calcium borogluconate (250 mg/ml), at a dosage of 1.5ml/kg body mass. The corrected ration should contain additional calcium carbonate, dicalcium phosphate, or sterilized bone meal, to give a final composition containing 1.5–2% calcium and a Ca:P ratio of 1.5:1 (Huchzermeyer, 2003).

Skin Diseases of Nile crocodiles In AMCR

Skin lesions were the second most common problems observed at AMCR after paralysis of hind legs (Mahammed, 2008). Dermatophilosis is one of the two-specific bacterial skin infections after Erysipelothrix. The other two known forms, ‘winter sores’, with yellow-brownish crusty lesions, and chronic stress dermatitis, with patches of white discoloration, particularly on the head around eyes and nostrils, are non-specific and many bacterial species can be involved. No occurrence of dermatophilosis has been reported, yet (Gilber, 2000; Huchzermeyer, 2003). Crocodile pox is one of the viral skin diseases of Nile crocodile, caused by Parapoxvirus. Based on the histopathological diagnosis of the skin lesions, showed the finding of the typical intra-cytoplasmic inclusion bodies. Moreover, fungal infections of the skin occur either locally or generalized under unhygienic conditions in animals with reduced immune capacity due to stress or cold. Superficial infections in the epidermis do not provoke much of an inflammatory response. Deeper infections cause a granulomatous reaction and not an exudative one (fibriscess), as in the case of bacterial infections. The treatment of deep granulomatous lesions may need the application of systemic fungicides, such as ketoconazole. There is no specific treatment; hygienic sanitation is the best prevention provision (Gilber, 2000; Huchzermeyer, 2003).

CONCLUSION AND RECOMMENDATIONS

Crocodylus niloticus is found in 26 African countries, including Ethiopia. In 1972 commercial hunting of crocodiles was prohibited in Ethiopia and C. niloticus was listed the Nile crocodile in Appendix II of CITES. The decreasing number of species in AMCR affected by low management skills, environmental factors, anthropogenic effects, health problems, and misguided hunting. The isolated causative agents of the species abnormalities require more attention and commitment to resolve the problems. Infectious diseases of bacterial, viral, parasitic, and fungal infections have to be managed wisely and crocodile farmers and other stakeholders in the crocodile industry must focus on causes of the degenerative and
metabolic disorders. EWCA is losing its foreign currencies income from consumptive and non-consumptive advantages. In conclusion, the office of AMCR must work with professionals and research groups. Besides, the Arba Minch Crocodile Ranch (AMCR) should exercise care and caution when introducing hatchlings from the wild into the Ranch and enhance its husbandry methods to reduce the occurrence of infection and disease. The recommendations by Crocodile Specialist Group (CSG) on Management of Crocodile in Ethiopia should be addressed and implemented.
