Supporting Information

ABSTRACT: This study aimed to compare the histomorphometric and histochemical features of the duodenum twenty sheep (n=10) and rabbit (n=10) adult males. The samples were collected from slaughterhouse and markets of Misan and were used for histological studies of two types of stains, hematoxylin and eosin, and special stains (Periodic acid Schiff stains). In histological approach, in both animals, the wall of the duodenum consists of four layers (mucosa, submucosa, muscularis and serosa). In both animals, the mucosa of the duodenum lined by simple columnar epithelium and has number of villi compose of absorptive (enterocytes) and goblet cells only in duodenum, the submucosa occupied by Brunner’s glands. Brunner’s glands are varying in secretory unit acinal in rabbit serous and mucous acini while in sheep the mucus acini. There is significant difference in thickness of layers between sheep and rabbits. Mucosa, sub mucosa and muscularis layers in sheep showed more thickness than in rabbits, but there is non- significant (P>0.05) differences between the thickness of the serosa in sheep and rabbit in the duodenum. On the other hand, the columnar cells showed a weakly reaction with Periodic acid Schiff stain (PAS), but goblet cells in sheep and rabbits shown strong reaction with PAS. While the Brunner’s glands were strong reaction with PAS in sheep and weakly reaction with PAS in rabbit. In conclusion, this study showed that sheep and rabbits have similarities and differences in the duodenum; that is, the layers of this organ has different thicknesses and respond differently to periodic acid Schiff stain.

INTRODUCTION

Evolution between animals causes many changes so that it can adapt to its environments. Each animal species has unique characters that help them survive and can consume different types of feed (Salama et al., 2019). Rabbits are considered economically significant animals as they have the advantage of their meat and furring, are used as pets, and they are substantial at scientific and medical experiences (Salama et al., 2019). On the other hand, sheep have been able to use lignocellulosic materials and convert them to animal products of high nutritional value, such as meat, milk, wool/fur, hide, and manure (Saeed et al., 2018). Fermentation organs are depend on a symbiotic relationship with a community of microbes, primarily bacteria with fibrinolytic ability in either their foregut (which the rumen of ruminants and the pseudo-ruminants) or their hindgut (which the cecum and colon of non-ruminant herbivores), for fiber digestion (Crowley et al., 2017; Kingston-Smith et al., 2012).

Given the comparative investigations of the digestive tract it can be said that the level of development of each segment is directly related to the living environment, nutritional and metabolic needs (Kotze et al., 2010). The small intestine is a long, tubular organ, connects the stomach to the large intestine and can be divided into duodenum, Jejunum and ileum based on anatomy and function, the duodenum is a tiny fraction of the small intestine, it is the site of most of the breakdown of the food passing through it, the duodenum is line with duodenal sub mucosal glands, which secrete an alkaline mucus that supports the intestinal enzymes and aids in the absorption of nutrients (Cunningham and Klein, 2007). In histological approach, the duodenum wall has four concentric layers: mucosa, submucosa, muscularis and serosa, and this structure have also been observed in other mammalian species (Gadelha-Alves et al., 2008). The surface epithelium of small intestine is covers by the villi which are already protruded into the intestinal lumen and it also lines the crypts which are extended to the connective tissue (Mohamed et al., 2019). Kadadi (2012) described that the villi are finger like projections forms of a core of reticular tissue covers by surface epithelium. Also, among the villi are small openings of the simple tube glands called the intestinal glands (crypts of Lieberkühn). Whereas, Al-Shamary et al. (2017) stated that the crypts of Lieberkühn are simple tubular glands called intestinal glands that were extend from the muscularis mucosa till the bases of the villi, they were lined by a simple columnar epithelium. Calamar et al. (2014) reported that the sub-mucosa tunica is formed of loose connective tissue and provides support for the vascular and nerve network. The Brunner’s glands: are branched tubuloalveolar glands, located in sub mucosa, they existed at each
mammalian species (AL-Baghdady et al., 2012). The muscularis layer of small intestine composes of two layers of smooth muscle cells internal-circular and external-longitudinal (Calamar et al., 2014). The intestine has no serosa, the layer external to the tunica muscularis would be referred to as the adventitia (Nzalak, 2010).

This study aimed to compare the histomorphometric and histochemical similarities of the duodenum of sheep (herbivorous ruminant) and rabbit (herbivorous and coprophagous).

**MATERIALS AND METHODS**

**Surgical procedures**

The present study was carried out in the department of biology Sciences at the University of Misan. A total of ten sheep, adult males, were collected from local slaughterhouses and ten rabbits, were weight of 1.5 - 2.5kg and their age is almost three months adult males, were collected from Misan city. The experiments on rabbits followed the guidelines provided by the University's Animal Ethics Committee. The rabbits were raised under standard procedures and euthanized following the animal euthanization protocol. A physical examination was performed to all animals to guarantee they were all in the right health conditions before the euthanasia. The euthanizing procedures were done by placing 2 mL of chloroform (CHCl3) on cotton and then set on the animal's nose, according to Blackshaw et al. (1988). By using appropriate tools as scissors, tweezers and scalpels regional gross dissection was performed of each specimen. The abdomen of the rabbits was incised, and the duodenum extracted. Then, taken 1 cm from duodenum.

**Histological examination**

All duodenum samples of rabbits and sheep were fixed in 10% neutral buffered formalin promptly. After fixation for 72 hours, all samples were processed with a series of ascending ethanol concentrations (70%, 2h. 80%, 30min. 96%, three changes, 2h each. 100% absolute, 9h than 100% hour) to dehydrate them. Then, all samples were cleared with xylene for one hour and embedded in paraffin wax to make paraffin blocks. Finally, sections were cut at 7-micrometer thickness and processed with two stains (Luna, 1968). Hematoxylin and Eosin and Periodic Acid-Schiff (PAS) stains were used to stain all tissue sections for histomorphometry identification and carbohydrates determinations, respectively (Luna, 1968).

**Micromorphometric measurements**

Ten slides were made duodenum, and to detect the thickness of mucosa, submucosa, muscular, and serosa, we followed the literature methods which by using the optical microscope with the exact ophthalmic scale (ocular micrometer) after the exact ophthalmic scale was matched with the theatrical scale using the magnification force (Galigher and Kozloff, 1964).

**Statistical analysis**

The values were expressed as mean ± SD (standard deviation). The statistical analysis of the data was performed to know the significant differences using t-test at P<0.05 of probability (Al-Rawi and Khalaf Allah, 2000).

**RESULTS and DISCUSSION**

**Histological study**

Histological examination results show that the mucosa of duodenum has number of villi compose of absorptive (enterocytes) and goblet cells only (Figures 1 and 2). The columnar cells have nucleus round found in near the base, and cytoplasm was eosinophilic, while goblet cells are unicellular in its apical part becomes puffy due to mucigen droplets accumulation and have nucleus is irregularly oval or triangular at the base and in both species have same characteristic, and cytoplasm seen clear post staining with hematoxylin and eosin stain. These results are similar to the study of Parveen et al. (2013). However, the stem cells give rise to 4 major epithelial cells: the absorptive enterocytes which make up about 80% fall small intestinal epithelial cells; the goblet cells which produces a variety of mucins and trefoil peptides needed for epithelial growth and repair; the enteroendocrine cells which export peptide hormones; and the paneth cells which secretes antimicrobial cryptdins or defensins, digestive enzymes, and growth factors (Korkmaz and Kum, 2016). Ergun et al. (2003) stated that absence paneth cells in the villi of small intestine and that these cells were differentiated as such toward the base of the crypts. Lamina propria: in both animals consist from loose connective tissue containing blood vessel, nerves, lymphatic assemblies, and the intestinal glands or called crypts of lieberkuhn extended to below muscularis mucosa and consists of the columnar cells, the goblet cells and the Paneth’s cells (Figures 5 and 6), these glands well developed appeared simple tubular and this finding similarity with (Hassan and Moussa, 2015). Mascolaris mucosa composed of smooth muscle fiber, it located at the base of the crypt is thin in rabbit but it thicker and very clear in sheep. Muscularis mucosa thin layer of circular smooth muscle fibers at the blow of the crypt but seen more thickness in sheep consistent with Lesson and Lessson (1988). Submucosa layer seen as a thin layer of loose connective tissue abundantly supplied by blood vessels, lymphocytes, collagen and elastic fiber ,it locate below mucosa layer, in the duodenum contains glands called (Brunner’s glands), Brunner’s glands are developed very increased in density in the sub...
mucosa of the duodenum sheep than in rabbit, these are simple tubular. Brunner’s glands are vary in secretory unit acini in rabbit serous and mucous acini where characterized by their relatively wide lumen and their cells appeared pale, while in sheep the mucus acini. In both animals sub mucosa only in the duodenum has Brunner’s glands are simple tubular. The duodenum is the site of most of the breakdown of the food passing through it (El-Nasharty et al., 2013). Brunner’s glands have function neutralizes chyme entering to the duodenum from the pylorus, protecting the mucous membrane, and bringing the intestinal contents to the optimum pH for pancreatic enzyme action (Emel et al., 2010). Hassan and Moussa (2015) reported that duodenum goat didn't exhibit any glands of Brunner at the sub mucosa layer nor did the sub mucosa of jejunum contain any glands or lymphoid nodules. The muscularis layer composed by an inner circular and an outer longitudinal layer of smooth muscles and between connective tissue, similar findings were reported in sheep (Kumar et al., 2015). The serosa layer formed by the loose connective tissue had collagen, elastic and also reticular fibers along with varying amounts of fatty tissue, few blood capillaries, and flat mesothelial cells layer as reported in domestic animals (Stinson and Calhoun, 1993).
**Histomorphometric study**

The thickness of sheep mucosa layer in the duodenum (2146.31±158.24) significantly (P<0.05) large in comparison to the duodenum of the rabbits where the value found were 846.84±55.03 (Table 1). The villi height in sheep in the duodenum (951.85±363.88) significantly (P<0.05) large in comparison to the duodenum sections of rabbit small intestine where the values found were 566.90±127.8 and 510.90±78.87 (Table 1) respectively. The thickness of sheep submucosa layer in the duodenum (228.61±54.77), significantly (P<0.05) large comparison to sections the duodenum of the rabbits where the values found was 58.32±16.49, respectively (Table 1). The thickness of sheep muscularis layer in the duodenum 264.22±101.37, significantly (P<0.05) was large in comparison to the same section of the rabbits where the values found was 69.99±29.99 respectively. There were non-significant (P>0.05) differences between the thickness of the serosa in sheep and rabbit in the duodenum (Table 1). In this respect, Mandir et al. (2005) consider that increase in thickness of intestinal epithelial tissue as well as the development of the gut itself can occur during three main mechanisms, that are elevation of cell production from the intestinal crypts, raise in number of crypt (by crypt fission) or by altered apoptosis. The thickness of the mucosa in rabbit duodenum (846.84±55.03) and this result disagree with study Tomaszewska et al. (2014), which observed in guinea pigs female mucosa thickness of duodenum was (488.3 ±99.81), this difference might be related to the nature of the nutrition intake of the animals. Alves et al. (2004) reported that measurements of villi height give an indication of the likely maturity and functional capacity of enterocytes Vili height was in the mucosa duodenum of rabbit was 566.90±127.81 and this result accordence with study of Yu and Chiou (1997) which was their result (543±15) in rabbit. As wall this result disagrees with Mohammadpour (2011) observed vili high of guinea pig in mucosa duodenum was 785.00±87.67, this difference might be related due vary in species.

**Histological study**

In both animals, the columnar cells gave a weakly reaction with PAS (Figure 7) and this may be indicate a lack of mucus secretion by these cells and this finding consistent with study of Andleeb et al. (2009). Goblet cells in sheep and rabbits, these cells gave strong reaction with PAS and this is evidence of neutral mucus in duodenum. Moreover, Kadadi (2012) stated that duodenal goblet cells in sheep stained with magenta indicating presence of PAS positive material in their secretions. Jawad et al. (2019) stated that crypts of Lieberkuhn in the tunica mucosa of the duodenum in rabbits positive reaction with PAS. In addition, Brunner’s glands of the sub mucosa layer in gave a strong reaction with PAS in sheep duodenum (Figure 7), while in the rabbits were Brunner’s glands mixed gland (serous cells a weak reaction with

PAS and mucous cells moderate reaction with PAS (Figures 8 and 9). Kadadi (2012) which reported that Brunner’s glands in sheep showed positive reaction with PAS. However, Sub-mucosal glands are varying with species and there are three types of acini (mucus, serous and mixed). In previous studies; Mohammadpour (2011) and Krause, (2000) observed that Brunner’s glands in Guiana pig and moose they mucos acini only. The studies uses different techniques depend on species, duodenal sub-mucosal glands were reported to contain neutral or acidic mucin glycoproteins or the combination of both types of mucin (Takehana et al., 1991; Krause, 2000). Andleeb et al. (2009) reported that Brunner’s glands in Gaddi goat gave strong reaction with PAS and this is evidence of the presence of neutral carbohydrates.

**CONCLUSION**

These findings indicated similarities and some different between herbivores species. In sheep and rabbits, the duodenum is composed of four layers: mucosa, submucosa, muscular, and serosa. In both animals, in duodenum, the submucosa is occupied by Brunner’s glands. Brunner’s glands are vary in secretory unit acini in rabbit serous and mucous acini while in sheep the mucus acini. There is significant difference in thickness of layers between sheep and rabbits. Mucosa, submucosa and muscularis layers in sheep showed more thickness than in rabbits, but there is non-significant differences between the thickness of the serosa in sheep and rabbit in the duodenum. On the other hand, the columnar cells showed a weakly reaction with PAS, but goblet cells in sheep and rabbits shown strong reaction with Periodic acid Schiff stains (PAS). While the Brunner’s glands were strong reaction with PAS in sheep submucosa.
